## Abstract

Superconducting Tunnel Junctions (STJ) are currently being developed as photon detectors for a wide range of applications. Interest comes from their ability to cumulate photon counting with chromaticity (i.e. energy resolution) from the Near InfraRed (NIR) to the X rays wavelengths and excellent quantum efficiency up to 80%. Resolving power can reach more than 10 in the visible. Our main goal is to use STJ for astronomical observation at low light level in the near infrared.

This paper relates mainly to two points : The improvement of the Tantalum absorber epitaxy and the development of a new version of the fabrication process for making Ta/Al-AlO<sub>x</sub>-Al/Ta photon counting STJ. The main features of this process are that pixels have aligned electrodes and vias patterned through a protecting SiO<sub>2</sub> layer. This vias are then used to contact the top electrode layer. We use a double thin aluminum trapping layer on top of a 150 nm thick Ta absorber grown epitaxially. © 2001 Elsevier Science. All rights reserved

## 1. Introduction

Superconducting Tunnel Junctions (STJ) have shown their capability to count photons in the NIR with a moderate energy resolution [1]. Astronomers now use STJ as photon counting cameras having intrinsic and moderate energy resolution [2].

The aim is to investigate the interest of this kind of detectors for astronomical applications and compare them to Hot Electron Bolometers devices (or Superconducting Single Photon Detectors, SSPD) that are also developed in our group [3]. Since the conventional detector arrays based on semi-conductor devices have progressed recently toward the direction of photon counting detectors [4], some niches have to be found for this type of detectors where

conventional devices cannot compete. The expected astronomical applications that would be investigated are wave front sensing detectors for adaptive optic system and interferometry (fringes sensors, focal plane instrument).

## 2. Junctions fabrication

We have developed an original fabrication process of Ta (150 nm) /Al-AlO<sub>x</sub>(1nm)-Al (80 nm)/ Ta (120 nm) superconducting junctions. The multilayer is deposited in-situ by DC-Magnetron sputtering except for the aluminum oxide barrier, which is obtained by static oxidation (200 mbar of pure O<sub>2</sub> atmosphere during 30 minutes). R-plane polished Sapphire is used as substrate since the square section presented on surface is particularly adapted to the cubic lattice of Ta and Nb. Since the Al energy gap is smaller than the Ta one (0.172 and 0.664 meV), the two aluminum layers are used to support the localization of the excited charges near the oxide barrier [5].

### 2.1. Absorber epitaxy improvement

Like a majority of photon counting detectors, STJ converts the incident energy into an excited charge population which gives an access to the deposited energy. Here, the photon-excited charges tunnel through the oxide barrier and the energy can be measured thanks to the integration of the induced current. Thus, the crystalline quality of the base Ta electrode (the absorber), in which the photons are absorbed, is a critical parameter and we need to maximize the lifetime of the excited charges.

Standard Ta sputtering on Nb buffer layer [6], in a background pressure of about 10<sup>-7</sup> mbar and at room temperature, gives polycrystalline film as shown on upper  $\theta$ -2 $\theta$  scan (see Fig. 1). By sputtering at 600 °C directly on sapphire, the film is more textured, but the orientation inside the growth plan is still too dispersed and diffraction peak intensity not improved [7]. Thus, we also use a thin Nb buffer layer (<10 nm) and high substrate temperature to nucleate the right cubic Ta phase (this buffer layer facilitates the relaxation of the cubic Ta lattice constant). We obtained a very significant improvement of the diffraction peak intensity. Thanks to Scherrer law, we

estimate grains' highness to 90 nm and Ta (200)  $\omega$ -scan gives angular dispersion of 0.3° with the growth axis.

Fig. 1.  $\theta$ -2 $\theta$  Scan of Ta Thin Film. Up: polycrystalline sputtered at room temperature. Down: Epitaxial at 600°C. Both on an Nb buffer layer.

The RRR measurement (Relative Resistive Ratio) confirms the improvement of the Ta quality: mean free path under 10K is increased by a factor 10 ( $l_{10k} = 160$  nm) [7].

### 2.2. Development of a dry etching process

The first four steps of this new process are detailed in the Fig. 2. The junction and absorber areas are defined together during the first step of this process by RIE (Reactive Ion Etching) for Tantalum and Ion Milling for Aluminum. Immediately after, an MgO/SiO<sub>2</sub> (400 nm) insulating film protects the entire wafer. The electrical contacts to the two junction electrodes are defined by holes etched by RIE into the SiO<sub>2</sub> film (1 nm MgO is used as etch stop and is etched by ion milling). With the third mask level, a Nb contact level is patterned also by RIE providing current leads and contact pads used for the junction connection to the electronics.

Then, the contact to the absorber layer is forced by the etching of a small band (3  $\mu$ m wide) of the Ta/Al-AlO<sub>x</sub>-Al films. The etching process stops at the Ta absorber film.

Fig. 2. The different process steps (side view) and top view of the final device.

The main motivation for developing a new process compared to the previous one [7] are :

- The junctions passivation just after their definition which insures protection all along the process in the same logic as in advanced planarization techniques used in microelectronics.
- The exclusive use of controlled dry etching techniques rather than lift-off ones.
- The alignment of the two electrodes during the first step etching which reduce the absorber exposed surface states .

### 3. Conclusion

A dry etching version of the process has been developed for the fabrication of Ta-based STJ to be used as photon counting detectors for astronomical applications. The tantalum superconducting quality has been significantly improved by the introduction of a niobium buffer layer and reaches high quality epitaxy.

The results of the first wafers fabricated with this new process are promising despite we still have to optimize the oxidation conditions. They validate the different process steps and assure the feasibility of STJ with it. This process improve the quality, the reliability and the wafer homogeneity of the junction fabrication. The produced Ta STJ's will be tested as photon counting devices and evaluated in the framework of astronomical instrumentation. They will also be compared to other superconducting devices (SSPD) that are produced in our group.
